The Armington Elasticity: from a micro-level data

Resumé:

The paper presents substitution elasticities for Danish imports at the most detailed level of SITC-aggregation estimated using Feenstra (1994). The elasticities describe the substitution between foreign varieties, for example, the substitution between imports from Germany versus imports from UK. The sectoral estimates show much heterogeneity and range between -1.14 and -32.65 with overall mean -6.15 and median -4.45. The weighted averages of the sectoral estimates range between -3.82 and -6.83 using expenditure shares as weights, and between -2.58 and -5.82 using standard errors as weights. The point elasticity estimates are very close to an average estimate obtained from a bootstrapping procedure.

1. Introduction

The Armington elasticity of substitution between differentiated goods is one of the most empirically studied topic in international trade. Despite a large body of literature, there is no consensus on the magnitude that should be used, for example, in macroeconomic models. Orcutt (1950), Houtakker and Magee (1969) and Goldstein and Khan (1985) are some of the most sited early studies.

There has been an increasing research based on microeconomic data and the corresponding estimated elasticities tend to be larger than macro-data-based estimates, see Feenstra (1994), Broda and Weinstein (2006), Corbo and Osbat (2013) and Imbs and Mejean (2015). Imbs and Mejean (2015) show that the difference between macro and micro estimates is due to heterogeneity bias in aggregate data that pushes the macro estimate downward. Large price changes tend to occur in inelastic products, causing the aggregate price change to be associated with little response in quantities and resulting in low aggregate elasticity estimates.

This paper presents substitution elasticities for Danish imports estimated using the most detailed level of SITC aggregation. The paper uses the estimation technique proposed in the seminal work of Feenstra (1994). Feenstra supplements the demand equation for imports with a supply equation to account for the endogeneity of prices and applies the generalized method of moment estimator. In some instances, Feenstra's method generates elasticities that take on imaginary values that are outside the theoretically justified boundaries. For these groups we apply the grid search technique proposed by Broda and Weinstein (2006).

Previously, to the best of my knowledge, two studies have estimated elasticities of substitution for Danish imports at highly disaggregated level. Mohler and Seitz (2010) report a median elasticity of 3.42 using detailed data based on the Harmonized System and Corbo and Osbat (2013) using ISIC dataset report an average elasticity of 4 for Danish imports. The estimated elasticities in this paper range between -1.14 and -32.65 with overall mean -6.15 and median -4.45.

The next section briefly presents the theoretical model based on the workings of a Constant Elasticity of Substitution (CES) function. Section 3 presents Feenstra's (1994) Instrumental Variable (IV) procedure for estimating the Armington elasticity of substitution between varieties. Section 4 presents the dataset and the associated issues from using unit values as substitutes for price indices. Section 5 presents selected estimation results for the import-demand equations and a complete list of the estimated results is provided in the Appendix. Finally, section 6 concludes.

2. The model

The estimation strategy is based on Feenstra (1994). Feenstra uses the standard CES setting to derive demand equation for imports, the model implies the following import demand equation:¹

$$x_{it}^{k} = \frac{1}{\beta_{it}^{k}} \left(\frac{P_{it}^{k}}{P_{t}^{k}} \right)^{-\sigma^{k}} x_{t}^{k}, \tag{1}$$

Where x_{it}^k is the variety *i* of good *k* consumed at time *t*, as in Armington (1969) a variety i = 1, ..., N is distinguished by supplying country, i.e., there are as many varieties of *k* as there are trading partners. x_t^k is the total consumption of good *k* at time *t*, P_{it}^k is the price of x_{it}^k and P_t^k is the aggregate price for x_t^k . σ^k is the Armington elasticity of substitution assumed to be greater than unity and constant over all varieties.

Feenstra writes (1) in terms of expenditure shares, which helps to reduce measurement errors that arise from using unit values as substitutes for import prices (Kemp, 1962). Let $s_{it}^{k} \equiv \frac{P_{it}^{k} x_{it}^{k}}{\sum_{i} P_{it}^{k} x_{it}^{k}}$ denote the market share of country *i* in expenditures on good *k*, the demand equation can be written in terms of expenditure shares as:

$$\Delta lns_{it}^{k} = \emptyset_{t}^{k} + (1 - \sigma^{k})\Delta lnP_{it}^{k} + \varepsilon_{it}^{k}$$
⁽²⁾

The intercept \emptyset_t^k is time-varying and contains the variables that are common to all varieties. ε_{it}^k is the error term combining preference shocks and trade costs.

In order to estimate σ^k consistently, the error terms ε_{it}^k must be uncorrelated with the expenditure shares and prices. However, due to the simultaneous determination of import prices and quantities, it is likely that the error term can be correlated with Δlns_{it}^k and ΔlnP_{it}^k . To account for the simultaneity bias, Feenstra proposes using a supply function together with the demand function. The supply curve is specified as:

$$P_{it}^{k} = \exp(v_{it}^{k})(x_{it}^{k})^{\frac{\omega^{k}}{1-\omega^{k}}}$$
(3)

Where $\omega^k \ge 0$ is the inverse supply elasticity in sector k, assumed to be equal across all countries. v_{it}^k is the technology shock independently and identically distributed across countries and assumed to be independent of ε_{it}^k . Like the demand equation, the supply equation can also be re-written in terms of expenditure shares as:

$$\Delta ln P_{it}^k = \varphi_t^k + \omega^k \Delta ln s_{it}^k + u_{it}^k \tag{4}$$

¹The derivation of a demand function based on a CES utility function is well-known, see Feenstra (1994) and Broda and Weinstein (2004) for a detailed exposition.

Where φ_t^k is a time-varying intercept common across countries and $u_{it}^k \equiv \Delta v_{it}^k (1 - \omega^k)$ is an error term that depends on supply shocks. Equation (2) and (4) can be consistently estimated by exploiting the panel structure of the data without a need for external variables. The technique is based on Leamer's (1981) time series estimation of a system of demand and supply equations without instruments. The CES structure implies that the substitution elasticity for a given good k is constant across importing countries, and if the supply elasticity is constant across supplying countries, a hyperbola of elasticity estimates can be obtained by using time series data for each country. By combining the elasticity estimates over all countries, multiple hyperbolas are obtained whose intersection defines the demand and supply elasticities.

3. Estimation technique

For estimation it is convenient to eliminate the time-varying random terms ϕ_t^k and φ_t^k from the demand and supply equations, we choose a reference country r and take differences in demand and supply relative to the reference country, to arrive at:

$$Y_{it}^{k} = \theta_{1}^{k} X_{1it}^{k} + \theta_{2}^{k} X_{2it}^{k} + e_{it}^{k}$$
(5)

Where
$$Y_{it}^k = (\Delta lnP_{it}^k - \Delta lnP_{rt}^k)^2$$
, $X_{1it}^k = (\Delta lns_{it}^k - \Delta lns_{rt}^k)^2$, $X_{2it}^k = (\Delta lnP_{it}^k - \Delta lnP_{rt}^k)(\Delta lns_{it}^k - \Delta lns_{rt}^k)$, and $e_{it}^k = -(\varepsilon_{it}^k - \varepsilon_{rt}^k)(u_{it}^k - u_{rt}^k)/(1 - \sigma^k)$

Endogeneity is an issue in equation (5), since the demand shocks ε_{it}^k and the technological shocks u_{it}^k are correlated with prices and expenditure shares, the shocks embedded in ε_{it}^k are correlated with X_{1it}^k and X_{2it}^k .

Feenstra (1994) uses an instrumental-variable (IV) estimator where the instruments are dummy variables across the countries $i \neq r$.² Let $T_i^k \leq T^k$ be the total number of time periods country-*i* supplies good-*k*, then the total number of observations for good-*k* is $L^k \equiv \sum_{i \neq r} (T_i^k - 1)$, we subtract 1 so that the first differences in (5) can be calculated. We can now stack (5) over time and supplying countries and write:

$$Y^k = \theta^k X^k + e^k \tag{5*}$$

$$\bar{Y}_{i}^{k} = \theta_{1}^{k} \bar{X}_{1i}^{k} + \theta_{2}^{k} \bar{X}_{2i}^{k} + \bar{e}_{i}^{k}$$
(5')

We can run weighted least square (WLS) on (5') and derive consistent estimates for θ_1^k and θ_2^k .

²Equivalently Weighted Least Square (WLS) can be used to obtain consistent estimates, cf Feenstra (1994). Provided ε_{it}^k and u_{it}^k are uncorrelated across countries, the time average of e_{it}^k is zero. The time averages of X_{1it}^k and X_{2it}^k , denoted \overline{X}_{1i}^k and \overline{X}_{2i}^k , can be used as instruments to derive a consistent estimator. Since $cov_{it}(\overline{X}_{1i}^k, e_{it}^k) = cov_{it}(\overline{X}_{2i}^k, e_{it}^k) = 0$, the endogeneity issue is remedied, and identification is effectively obtained across countries. Take the time averages of the variables in (5) and write:

Where Y^k is an Lx1 vector with components Y_{it}^k , X^k is an Lx2 matrix with components (X_{1it}^k, X_{2it}^k) , and e^k is Lx1 vector with components e_{it}^k . Let Z^k denote the instrument matrix for X^k . It contains dummy variables for each variety $i \neq r$, and takes the form:

$$Z^k \cdots \begin{bmatrix} l_1^k & \cdots & 0\\ \vdots & \ddots & \vdots\\ 0 & \cdots & l_{N-1}^k \end{bmatrix}$$

Where l_i^k denote a $T_i^k x^1$ vector of 1's for $i = 1, ..., N - 1, i \neq r$. Then the usual IV estimator will provide consistent estimates of θ^k . To obtain efficient estimates, we use a weighted IV estimator. That is the observations in (5*) are weighted by the variances of the residuals obtained from (5) using the first stage $\hat{\theta}$ estimates. Finally, we include a constant term in (5*) to control for measurement errors arising from the use of unit values as price indices.

Once a consistent and efficient θ_1^k and θ_2^k are estimated, the demand and supply price elasticities can be obtained by solving the quadratic equations:

$$\theta_1^k \equiv \frac{\omega^k}{1 - \sigma^k} \text{ and } \theta_2^k \equiv \omega^k + \frac{1}{1 - \sigma^k}$$
(6)

If $\theta_1^k > 1$, irrespective of θ_2^k there will be two solutions to the demand elasticity, one that is greater than one and another less than one, we focus on the case $\sigma^k > 1$. If, however, θ_1^k is negative, we cannot get theory-consistent values for demand and supply elasticities in the range $\sigma^k > 1$ and $0 \le \omega^k < 1$. Feenstra (1994) discards these sectors. We follow Broda and Weinstein (2006) and perform a grid search over the range of possible values, see also Imbs and Mejean (2015) for application. We conduct a grid search over the values of σ^k and ω^k in the range $\sigma^k > 1$ and $0 \le \omega^k < 1$ looking for the minimum sum of squared Weighted Least Square residuals. We evaluate the weighted sum for values $\sigma^k \in (1, 80]$ with 5 percent increment and values $\omega^k \in (0.01, 0.99)$ with 0.01 increment. The resulting combination of σ^k and ω^k that minimizes the weighted sum of residuals is the optimal solution.

4. The data

The data is obtained from OECD's International Trade by Commodity Statistics database (ITCS). The database provides detailed annual data classified by SITC for 1989 to 2014. Imports and exports both in value and quantity are reported for Danish trade with approximately 230 partners. Trade values are reported in current USD and quantities are reported in various units of measurement such as area in square meters, electrical energy in thousands of kilowatt-hours, etc.

The calculation of unit values that are used as a proxy for prices is made difficult at least for two reasons: first, there is no simple way of converting different units of measurement into a single measure, and second, missing values and outliers are common at the highest level of disaggregation. The proposed estimation technique (see above) uses growth rates of unit values, which has the advantage that, if a unit value changes level due to a change in the unit of measurement, the year-on-year growth rate in the unit value is only affected in the year(s) where the unit of measurement changes. Thus estimation is still possible if the year(s) with changes in the unit of measurement are excluded.

The Hidiroglou-Berthelot (1989) method is used for outlier detection and deletion in the unit values. We define an outlier as a unit value growth rate with a so-called suspicion value above the permitted threshold. First, suspicion values are calculated for growth rates outside the first and third quartile. The suspicion value is the distance of a given growth rate from the nearest quartile relative to the interquartile distance. Then, growth rates with a suspicion value above a threshold of 1.5 are replaced by zero.³

The use of disaggregated data presents additional problems. The identification strategy requires the availability of a reasonable number of trading partners supplying Danish imports consistently for a reasonable number of periods. However, the continued rise and fall of trading partners makes it difficult to calculate a time series of bilateral unit values at the most detailed level. Alternatively, we can choose to work with a higher aggregation level, but then we will be introducing heterogeneity bias. To avoid this bias, we use data at the most disaggregated level and impose a minimum of 15 countries supplying imports for at least half of the sample periods. Imbs and Mejean (2015) used a minimum of 20 trading partners for estimating demand equation for US imports, but needless to say US has more trading partners than Denmark. In addition, we also impose a restriction on the expenditure shares, i.e. the trading partner in question should at least supply 0.1 percent of the total Danish imports for that particular commodity. To construct the variables in equation (5) we also need to choose a reference country which is used to eliminate terms common to all varieties. We have used Germany for reference country as it supplies imports for most commodities in the sample periods considered.

The OECD's ITCS database contains 3131 groups at the most disaggregated SITC (revision 3) level, using our criterion we are able to estimate sectoral elasticities for 127 commodities.

5. Results

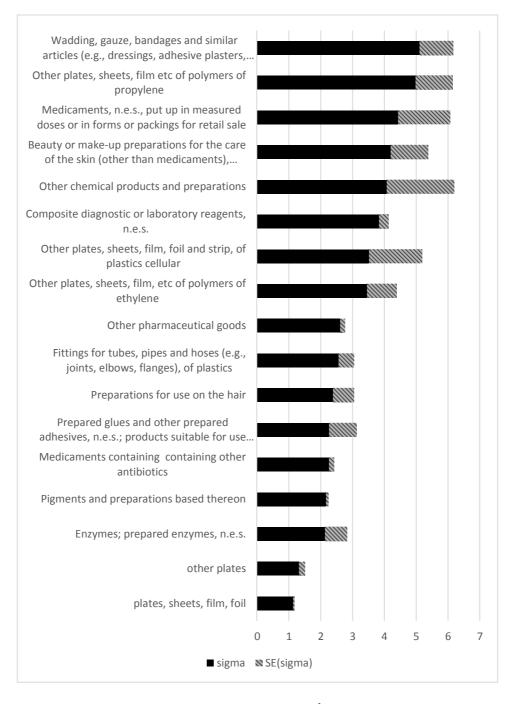

We present here commodity level elasticity of substitution estimates for imports using the method in Feenstra (1994). Table 1 presents elasticity estimates for food and live animals (SITC-0), beverages and tobacco (SITC-1) and raw materials (SITC-2). For SITC-0, the estimates range between -2.27 and -19.02, with mean -7.5 and median -5.26. There are only a handful of commodities in SITC-1 and SITC-2 and calculation of quartiles might be inappropriate.

 $^{^{3}}$ The choice of 1.5 is ad-hoc, Temere (2016) uses different suspicion values and shows that the result is not that sensetive.

Table 1. Elasticity of substitution estimates $(1-\sigma^k)$ for SITC-0, SITC-1 and SITC-2

Figure 1 presents the elasticity estimates for SITC-5 and similar figures for SITC-6, SITC-7 and SITC-8 are reported in the appendix. In general, the figures show a positive correlation between the numerical value of the elasticities and their standard errors, but there are also sectors with high elasticity and low standard error.

Table 2 provides summary statistics for the estimated elasticities. For each group, the summary statistic is calculated with and without the sectors with $\theta_1^k < 0$, i.e. we check the sensitivity of the averages to the grid search technique proposed by Broda and Weinstein (2006). Including the sectors with a negative θ_1^k coefficient does not significantly affect the estimated average elasticities.

The micro level estimates in this paper are not significantly different from similar estimates in the literature. Feenstra (1994) estimates substitution

elasticities for eight goods that are in the range -2.29 and -42.9. Corbo and Osbat (2013) using the ISIC-classification report an average elasticity of -4 for Danish imports, which is close to the overall median of -4.45 in this paper. Broda and Weinstein (2006) using the same methodology for US imports by SITC report a mean of -4.9 and a median of -2.0. The -4.9 is within the range of mean estimates reported in table 2 below, but their median estimate is significantly lower than ours. Imbs and Mejean (2015) report a mean of -5.4 and a median of -3.9 using 56 ISIC sectors for US imports, which is close to our estimates.

	Grid search	Mean	1st Quart.	Median	3rd. Quart	Min	Max	No. goods

Table 2	. Summary	statistic (no	o weights)
---------	-----------	---------------	------------

The ultimate purpose is to obtain aggregate elasticities implied by the micro estimates. A first approximation is to use the unweighted means and medians as provided in table 1. However, this approach can be easily refuted as it assumes the same elasticity for all sectors. An alternative is to make weighted averages using the expenditure shares of each good as weights. One can also argue that the elasticity estimates should be weighted by the inverse of their standard errors, i.e. a sector with low standard error should be proportionally assigned a higher weight. Table 3 presents weighted average elasticities.

Table 3. Summary statistic, weighted averages

	expenditure sh	ares as weights	standard errors as weights		
	agg. elasticity	agg. elasticity ^(a)	agg. Elasticity	agg. elasticity ^(a)	
SITC-0	7,465	6,363	4,446	5,819	
SITC-1	1,808	-	1,768	-	
SITC-2	5,075	-	^(b) 3,770	-	
SITC-5	3,696	3,824	2,037	2,581	
SITC-6	6,277	4,372	2,942	3,079	
SITC-7	14,544	6,832	^(b) 3,919	4,313	
SITC-8	6,581	6,039	4,151	5,797	

^(a)Aggregate elasticities excluding sectors with the lowest two and the highest two elasticities.

^(b)In calculating the aggregate elasticities, it was necessary to exclude the SITC sectors 29193 and 77831 as they have very low standard errors and hence very high weights.

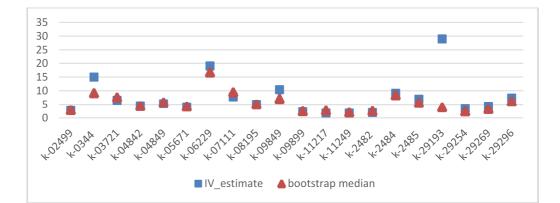

There is no systematic difference between the unweighted and weighted macro elasticities. For both SITC-6 and SITC-7 the expenditure-weighted average exceeds the unweighted average. The weighted aggregate elasticity of 14.5 for SITC-7 is quite large, and falls significantly to 6.83 if we exclude the sectors with the highest and lowest three elasticities. In fact, the aggregate elasticity is inflated due to the large elasticity estimated for motor vehicle imports that constitute about 30 percent of the expenditure on all SITC-7 sectors chosen for estimation.

The last two columns in table 2 present average elasticities weighted by the inverse of the standard errors. In contrast to the expenditure-weighted aggregates, it lifts the standard-error-weighted aggregates if we exclude the highest and lowest three elasticities. This is because most of the sectors with a high elasticity are also the ones with a high standard error and consequently a low weight. Yet another approach is to use a weight that is a composite of the expenditure share and the inverse standard error. Macro elasticities calculated in this way should lie between the two macro elasticities reported in table 3.

6. Bootstrapping

Bootstrapping techniques are used to assign measures of accuracy to sample estimates. Bootstrapping is useful when it is difficult to get different samples from a given population. A bootstrapping technique considers a sample as a population and draws a number of bootstrap samples with replacement that has the same size as the original sample. For each bootstrap sample, parameters of interest are calculated and afterwards measures of central tendency and dispersion can be calculated using the bootstrap estimates.

Here, bootstrapping is used to evaluate the original IV-elasticity estimates presented above. For each commodity k, we draw with replacement 10000 bootstrap samples of equal size to the original sample for equation (5), which is estimated 10000 times for each commodity k using the IV estimator described above. We keep only the bootstrap estimates for which $\theta_1^k > 0$, i.e. theory consistent values exist for the demand and supply elasticities. The median bootstrap estimate of the demand elasticity is calculated for each commodity and compared to the original IV-estimate, cf. figures 2 to 4 below. Each figure covers a group of commodities, and the estimated elasticities of each group are shown twice on different scales. With the largest scale, all estimates including outliers are visible, while the smaller scale is better for illustrating the typical difference between the original IV-estimate and the bootstrap median. The bootstrap medians are typically close to the original IV-estimates. For commodities where the two estimates differ, the bootstrap median should provide a better proxy to the unobserved true elasticity.

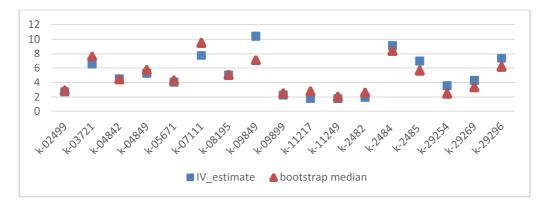

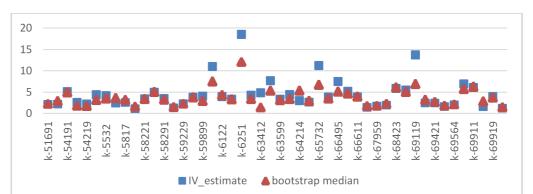

Figure 2. Elasticity of substitution estimates SITC-0,1&2 (upper panel: all estimates, lower: excluding commodities with high IV-estimates)

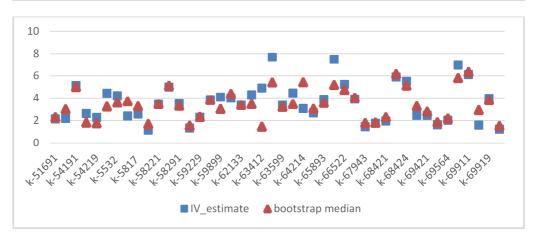

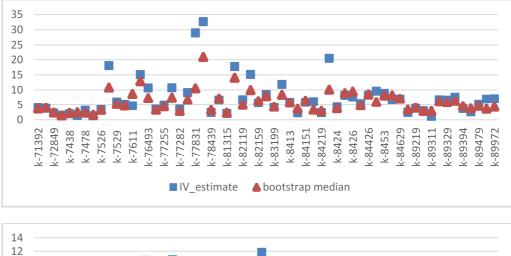

Figure 3. Elasticity of substitution estimates SITC-5&6 (upper panel: all estimates, lower: excluding commodities with high IV-estimates)

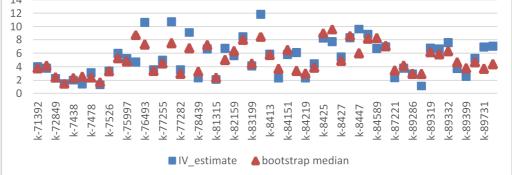

Figure 4. Elasticity of substitution estimates SITC-7&8 (upper panel: all estimates, lower: excluding commodities with high IV-estimates)

7. Conclusion

This paper has applied Feenstra's (1994) method for estimating elasticity of substitution for Danish imports at the most detailed level of SITC-aggregation. The detailed sector estimates have an overall mean of -6.15 and a median of - 4.45, which is not significantly different from the -4, which Corbo and Osbat (2013) estimated for Danish imports using ISIC data. The sector estimates are also aggregated using expenditure shares and standard errors of the estimated coefficients as weights. These aggregates range between -3.82 and -6.83 using expenditure shares as weights and between -2.58 and -5.82 using standard errors as weights. Moreover, a bootstrapping procedure indicates that the original point elasticity estimates are close to the bootstrap average, with the exception of a handful of outliers. The bootstrapping procedure also describes the distribution of the elasticity estimates.

The results of the different weighting schemes and the bootstrap indicate that a median of -4.45 is a robust estimate of the order of magnitude for the micro elasticity in Danish imports. This elasticity describes the substitution between countries supplying the import. The elasticity in the import relation of ADAM is significantly smaller and describes the substitution between import and Danish production.
